ABSTRACT

Adhesion of microorganisms to food processing surfaces and the problems it causes are a matter of strong concern to the food industry. Contaminated food processing surfaces may act as potential sources of transmission of pathogens in food industry, catering and in the domestic environments. Several studies have shown that adhesion of bacteria to surfaces partly depends upon the nature of the inert surfaces and partly upon the bacterial surface properties. The aim of this study was to compare the adhesion of four different strains of *Salmonella* Enteritidis to stainless steel 304 (SS 304). The effect of surface hydrophobicity and surface elemental composition on the adhesion process was also analysed. Hydrophobicity was evaluated through contact angle measurements using the sessile drop method. All the strains studied showed positive values of the degree of hydrophobicity (ΔG_{tot}) and so can be considered hydrophilic while stainless steel revealed a hydrophobic character. Bacterial cell surface composition was measured using X-ray photoelectron spectroscopy (XPS). The XPS results corroborated the similarity of the values of the degree of hydrophobicity obtained by contact angles. The different *Salmonella* strains showed similar elemental composition and cell surface physico-chemical properties. Nevertheless, *S. Enteritidis* MUSC presented higher adhesion ability to SS 304 ($p < 0.05$). It can be concluded that the physico-chemical properties of the strain does not explain the ability of adhesion to stainless steel. Other factors like the production of polysaccharides must be considered.

Key words: Adhesion, *Salmonella* Enteritidis, hydrophobicity

INTRODUCTION

Adhesion of microorganisms to food processing equipment surfaces is of great concern to the food industry. Adhered microorganisms to solid surfaces can have the potential to act as a chronic source of microbial contamination, which may compromise food quality and represent a significant health hazard (2). Several studies showed that cross-contamination can result from hands, sponges/clothes and utensils either in domestic kitchens or in any food processing plant (13,16,22,23). For instance, *Salmonella* spp. is able to colonize different inert food contact surfaces to form biofilms (3, 14, 18, 21). So, it has been recognized that a greater understanding of the interaction

between microorganisms and food-processing surfaces is required to control these problems.

Salmonellosis has been one of the most commonly reported food-borne illnesses worldwide. In many countries, including Brazil, *Salmonella* Enteritidis is the most frequently isolated serotype. Epidemiological evidence has linked the majority of outbreaks in State of Paraná, Brazil, to contaminated poultry products.

Stainless steel has been the material of choice for working surfaces and kitchen sinks for many years due to its mechanical strength, corrosion resistance, longevity and ease of fabrication (17). In the food processing industry most of the surfaces are of stainless steel including, pipelines and tanks (1), machinery

and working surfaces (18,26,28). Moreover, it is relatively resistant to chemical attack by oxidizing and other sanitizing agents used in the food industry, like hypochlorite, peracetic acid and iodophors (5).

The mechanisms governing the adhesion of *Salmonella* spp. to inert surfaces are not completely understood; several studies have shown that adhesion of bacteria partly depends upon the nature of the inert surfaces and partly upon the bacterial surface properties (7,9,19). Hydrophobicity and surface charge are the most important surface properties in the adhesion process as demonstrated by innumerable studies (18,25,27,32,36).

The understanding of microbial adhesion is of major importance in preventing undesirable biofilm formation. Therefore, the aim of this study was to compare the ability of adhesion of four strains of *Salmonella* Enteritidis to stainless steel 304 (SS 304), in order to investigate the behavior of different strains of the same species. The effect of surface hydrophobicity and surface elemental composition in the adhesion process was also analysed.

MATERIALS AND METHODS

Media and growth conditions

The strains used in this study are presented in Table 1.

All bacterial isolates were maintained in trypticase soy agar (TSA). Every strain was subcultured twice in trypticase soy broth (TSB) at 37°C in an orbital shaker (130 rpm), overnight. The cells were then harvested by centrifugation at 5000 g for 10 min and washed three times with phosphate buffered saline (PBS 0.1M pH 7). The pellets were resuspended in PBS to an inoculum level of 10⁸ CFU/ml, determined by optical density.

Material used as substratum

The test surface was stainless steel (304, finish n° 4), commonly present in the food industry and used in domestic kitchens. The coupons were cut in 0.8 x 0.8 cm², washed in a

solution of a commercial detergent (Sonasol Pril, Henkel Ibérica S.A., Portugal) in ultrapure water for 30 min and then thoroughly rinsed in ultrapure water (to remove any remaining detergent), followed by immersion in ethanol 90% for 30 min to completely degrease the surface and in sterile water.

Hydrophobicity and surface free energy

Hydrophobicity was evaluated through contact angle measurements and using the approach of van Oss and co-workers (37-39). In this approach, the degree of hydrophobicity of a given material (1) is expressed as the free energy of interaction between two entities of that material when immersed in water (w) - ΔG_{wl} . If the interaction between the two entities is stronger than the interaction of each entity with water ($\Delta G_{wl} < 0$) the material is considered hydrophobic. Conversely, if $\Delta G_{wl} > 0$ the material is hydrophilic. ΔG_{wl} can be calculated through the surface tension components of the interacting entities, according to:

$$\Delta G_{wl} = -2 \left(\sqrt{\gamma_l^{LW}} - \sqrt{\gamma_w^{LW}} \right)^2 + 4 \left(\sqrt{\gamma_l^+ \gamma_w^-} + \sqrt{\gamma_l^- \gamma_w^+} - \sqrt{\gamma_l^+ \gamma_l^-} - \sqrt{\gamma_w^+ \gamma_w^-} \right) \quad (1)$$

where γ^{LW} accounts for the Lifshitz-van der Waals component of the surface free energy and γ^+ and γ^- are the electron acceptor and electron donor parameters, respectively, of the Lewis acid-base component (γ^{AB}), with $\gamma^{AB} = 2 \sqrt{\gamma^+ \gamma^-}$.

The surface tension components of a solid material are obtained by measuring the contact angles of three pure liquids (one apolar and two polar), with well known surface tension components, followed by the simultaneous resolution of three equations of the form:

$$(1 + \cos \theta) \gamma_l^{\text{TOT}} = 2 \left(\sqrt{\gamma_s^{LW} \gamma_l^{LW}} + \sqrt{\gamma_s^+ \gamma_l^-} + \sqrt{\gamma_s^- \gamma_l^+} \right) \quad (2)$$

where θ is the contact angle and $\gamma^{\text{TOT}} = \gamma^{LW} + \gamma^{AB}$.

Contact angle measurements (at least 25 determinations with each liquid on stainless steel and on each microbial strain) were performed automatically with the aid of an image analysis system (G2/G40) installed in a standard contact angle apparatus (Kruss-GmbH). The images were transmitted by a video camera to a personal computer for evaluation. All the measurements were performed at room temperature. In the case of bacterial cells, the measurements were performed on a cell lawn using the sessile drop method described by Busscher *et al.* (6). Briefly, bacteria were deposited on a 0.45 µm cellulose acetate membrane filter by filtration of the suspension using negative pressure. To standardize the moisture content, the filters were then transferred onto Petri dishes containing 1% (w/v) agar with

Table 1. Bacterial isolates used in this study.

| Strains | Source |
|-------------------------------------------------|--------------------------------------------|
| <i>Salmonella</i> Enteritidis EMB ¹ | Water from poultry packaging |
| <i>Salmonella</i> Enteritidis MUSC ¹ | Breast meat of poultry |
| <i>Salmonella</i> Enteritidis AL ² | Food sample related to food-borne outbreak |
| <i>Salmonella</i> Enteritidis PC ² | Fecal human sample |

The bacterial isolates were obtained from:

¹Food Microbiology Lab., Depart. of Food and Dry Technology, University of Londrina, Pr, Brazil; ²LACEN (Central Paraná Public Health Laboratory Service).

10% (v/v) glycerol. Measurements of advancing water contact angles were carried out at 25°C and three liquids with different polarities were used, water (W), formamide (F) and α -bromonaphthalene (α -B). Their surface tension components were obtained from literature (20).

Hydrophobicity of the stainless steel was estimated by the same technique, with direct measurements of contact angles on stainless steel surface, after degreasing and cleaning.

X-ray photoelectron spectroscopy

Bacterial cell surface composition was measured using X-ray photoelectron spectroscopy (XPS). The bacterial cells were grown in 200 ml TSB at 37°C under 120 rpm for 18 h and washed three times in deionized water by centrifugation (10 min at 5000 g and 4°C). A volume of 200 ml of a cellular suspension (10^9 cells/ml) was vacuum filtered through an acetate cellulose membrane of 45 μ m. The membrane, completely covered with cells, was immediately frozen with liquid nitrogen and then stored at -80°C until the subsequent step of lyophilization. Freeze drying was performed at 10 Pa, overnight. The samples were placed in a dessicator, at room temperature and immediately analyzed by XPS. The XPS analysis was performed using an apparatus ESCALAB 200A, with a VG5250 software and data analysis. The spectrometer used monochromatized Mg K α X-ray radiation (15.000 eV). The constant pass energy of the analyzer was 20 eV and it was calibrated with reference to Ag 3d_{5/2} (368.27 eV). The pressure during analysis was under 1×10^{-6} Pa. The spectra were recorded following the sequence C 1s, O 1s, N 1s, P 2p. The elemental composition was defined as the ratio between oxygen and carbon (O/C), nitrogen and carbon (N/C) or phosphorous and carbon (P/C).

Adhesion assays

The coupons of stainless steel were immersed in 2 ml of each bacterial suspension containing 10^8 CFU/ml. After 1 h at 25°C with constant shaking at 100 rpm, the coupons were rinsed twice with PBS to remove poorly adhered bacteria. An aliquot of 20 μ l/ml of a 4',6-diamidino-2-phenylindole (DAPI) solution was added to each coupon containing the plates and incubated for 30 min in the dark. After this time, the coupons were rinsed with sterile distilled water and the adherent microorganisms were quantified by automatic enumeration using epifluorescence microscopy. Thirty fields per coupon were scanned and the fluorescent cells were enumerated. Computerized image analysis software (Image-Pro Plus, Media Cybernetics) was used for the quantitative estimation of the adherent cells. All experiments were done in triplicate.

Statistical analysis

The resulting data were analysed using SPSS software (Statistical Package for the Social Sciences). One-way ANOVA with Bonferroni test was used to compare the number of

adhered cells. All tests were performed with a confidence level of 95%.

RESULTS AND DISCUSSION

The contact angles formed by the three liquids (water, formamide, and α -bromonaphthalene) on stainless steel and on bacterial lawns are present in Table 2.

The values of water contact angles for all *Salmonella* strains tested were quite similar (9.7° - 14.0°) and were somewhat lower than those reported in the literature (17° - 35°) (10, 30). The different serovars of *Salmonella* studied and the non-uniformity on bacterial surface may explain the results obtained in this study (11). The water contact angle value gives preliminary information about the degree of hydrophobicity of cells. The sample is considered hydrophobic or hydrophilic if the angle is higher or lower than 65°, respectively (40). According to this criterion, all *Salmonella* strains are hydrophilic whereas stainless steel is hydrophobic.

The values of the contact angles of the three liquids were used to calculate cell surface tension parameters and the degree of hydrophobicity (Table 3).

Table 2. Values of contact angles (in degrees) measured with water (θ_w), formamide (θ_f) and α -bromonaphthalene ($\theta_{\alpha-B}$) on stainless steel and on the different *Salmonella* assayed.

| | Contact angle (°) (\pm SD) | | |
|----------------------------|-------------------------------|-------------------|---------------------|
| | θ_w | θ_f | $\theta_{\alpha-B}$ |
| Stainless steel | 81.2 (\pm 0.9) | 60.0 (\pm 1.1) | 23.4 (\pm 0.5) |
| <i>S. Enteritidis</i> EMB | 10.8 (\pm 2.2) | 15.6 (\pm 1.8) | 26.1 (\pm 4.2) |
| <i>S. Enteritidis</i> MUSC | 13.5 (\pm 1.6) | 15.9 (\pm 2.3) | 27.6 (\pm 1.7) |
| <i>S. Enteritidis</i> PC | 14.0 (\pm 4.4) | 17.0 (\pm 3.2) | 31.7 (\pm 2.8) |
| <i>S. Enteritidis</i> AL | 9.7 (\pm 1.9) | 14.8 (\pm 2.6) | 27.2 (\pm 2.5) |

SD - standard deviation.

Table 3. Values of the components of surface tension (γ^{LW} , γ^+ , γ^-) and degree of hydrophobicity (ΔG_{lwl}) of stainless steel and bacterial cells.

| | Surface tension (mJ/m ²) | | | |
|----------------------------|--------------------------------------|------------|------------|------------------|
| | γ^{LW} | γ^+ | γ^- | ΔG_{lwl} |
| Stainless steel | 40.81 | 0.00 | 5.84 | -59.80 |
| <i>S. Enteritidis</i> EMB | 39.89 | 0.97 | 55.99 | 34.12 |
| <i>S. Enteritidis</i> MUSC | 39.49 | 1.07 | 54.41 | 32.15 |
| <i>S. Enteritidis</i> PC | 38.06 | 1.22 | 54.48 | 32.28 |
| <i>S. Enteritidis</i> AL | 39.50 | 1.05 | 55.84 | 33.79 |

The ΔG_{hwl} values obtained were very similar for all the strains tested being all strains hydrophilic ($\Delta G_{hwl} > 0$). From Table 3, it can be observed that all cell surfaces were predominantly electron donors (higher values of γ), with low electron acceptor parameters (γ^+).

Considering the values of water contact angle (81.2°) and $\Delta G_{hwl} = -59.8 \text{ mJ/m}^2$, the stainless steel assayed was hydrophobic, which is in accordance with several authors (12,30,33). A point to be noted is that stainless steel does not have an electron acceptor parameter but is only electron-donor (γ).

The chemical composition of microbial cells surface obtained by XPS spectra is usually expressed in terms of N/C, O/C and P/C ratios (35). The corresponding values for the microorganisms assayed are presented in Table 4. All strains used in this study exhibited high O/C values, ranging from 0.465 to 0.584, and low P/C values, ranging from 0.008 to 0.0137.

Microbial surface thermodynamics is a reflection of the physico-chemistry of bacterial surfaces, which is controlled by macromolecular components, e.g., lipo-polysaccharides, proteins and exopolymers, varying in quantity with growth conditions and from strain to strain. The amount of the macromolecular components can be represented by a variety of different functional groups (31,34). In previous works, cell surface hydrophobicity, assessed by water contact angle, was directly correlated with the concentration of nitrogen or carbon involved in hydrocarbon form and inversely correlated with the oxygen concentration (4,11,29). In this study, the water contact angle was directly correlated with the N/C ratio whereas hydrophobicity expressed as ΔG_{hwl} , was inversely correlated with the oxygen concentration. The XPS results corroborated the similarity of the hydrophobicity values. Cerca *et al.* (8) correlated the N/C ratio of *S. epidermidis* strains with cell surface hydrophobicity, with the less hydrophobic cells exhibiting the lower N/C ratio. The presence of proteinic appendages is often reflected in a high nitrogen concentration at the cell surface (29).

The number of cells of different strains of *Salmonella* Enteritidis adhered to stainless steel are presented in Fig. 1. The extent of adhesion of *Salmonella* MUSC was statistically different ($p < 0.05$) of the other strains.

Liu *et al.* (24) predicted that when both bacterial and support surfaces are hydrophobic, microbial adhesion is highly facilitated.

Table 4. Ratios of the major chemical elements of bacterial surface composition of the *Salmonella* strains obtained by XPS analysis.

| Strain | N/C | O/C | P/C |
|----------------------------|-------|-------|-------|
| <i>S. Enteritidis</i> EMB | 0.066 | 0.584 | 0.008 |
| <i>S. Enteritidis</i> MUSC | 0.118 | 0.465 | 0.009 |
| <i>S. Enteritidis</i> PC | 0.118 | 0.466 | 0.009 |
| <i>S. Enteritidis</i> AL | 0.114 | 0.479 | 0.008 |

Figure 1. Number of adhered cells to stainless steel 304.

If both bacterial and support surfaces are hydrophilic, microbial adhesion would proceed with difficulty. Thus, an increase in cell surface hydrophobicity would favor cell adhesion on both hydrophilic and hydrophobic supports surface. Also, Assanta *et al.* (1) suggested that *Arcobacter butzleri* could attach in higher numbers to surfaces with low surface free energy and *Aeromonas hydrophila* cells had a tendency to attach in high numbers to hydrophobic surfaces. However, in the present case, the extent of adhesion does not seem to be directly related with cell surface hydrophobicity, because the strains show similar values of ΔG_{hwl} (Table 3). A recent study by Henriques *et al.* (15), reported the increase in the number of adhered yeast cells to acrylic by an increase in the interactions between the electron-donor groups of acrylic and the electron-acceptor groups of cells. Once more this can not be the rationale to explain the different extents of adhesion displayed by the *Salmonella* strains assayed.

CONCLUSIONS

The different extent of adhesion of four *Salmonella* Enteritidis strains to stainless steel 304 could not be explained in terms of cell surface physico-chemical properties. Other factors might be governing the process of adhesion, namely the production of exopolysaccharides is worth to be investigated.

This study proves that adhesion is strongly strain dependent and in this sense the adhesion ability of *Salmonella* serovars can be considered a factor of virulence.

RESUMO

Adesão de *Salmonella enteritidis* a superfícies de aço inoxidável

A adesão de microrganismos a superfícies de processamento de alimentos e os problemas que daí resultam são matéria de grande preocupação para a indústria alimentar. Superfícies de processamento de alimentos contaminadas podem actuar como uma potencial fonte de transmissão de patogénicos na indústria alimentar, restauração e em ambientes domésticos. Diversos estudos têm demonstrado que a adesão de bactérias a superfícies depende, por um lado, da natureza das superfícies inertes e, por outro, das propriedades superficiais das bactérias. O objectivo deste trabalho consistiu na comparação da capacidade de adesão de 4 cepas diferentes de *Salmonella Enteritidis* ao aço inoxidável 304 (SS 304). Analisou-se também o efeito da hidrofobicidade e da composição elementar no processo de adesão. A hidrofobicidade foi determinada através da medição de ângulos de contacto usando o método da gota sésil. Todas as cepas apresentaram valores positivos do grau de hidrofobicidade (ΔG_{int}) podendo, assim, ser consideradas hidrofílicas enquanto o aço inoxidável revelou um carácter hidrofóbico. A composição elementar da superfície das células bacterianas foi medida através de espectroscopia de fotoelectrões X (XPS). Os resultados do XPS corroboraram a similaridade de valores do grau de hidrofobicidade obtidos por ângulos de contacto. As diferentes cepas de *Salmonella* apresentaram uma composição elementar e propriedades físico-químicas semelhantes. No entanto, a *Salmonella* MUSC apresentou uma capacidade de adesão ao aço inoxidável mais elevada ($p < 0.05$). Pode então concluir-se que as propriedades físico-químicas das cepas não explicam a capacidade de adesão ao aço inoxidável, devendo ser considerados outros factores tais como a produção de exopolissacáridos.

Palavras-chave: Adesão, *Salmonella Enteritidis*, hidrofobicidade
